Pipeline 3 — Full Deep Dive Notebook

Exhaustive method-by-method companion to the main submission. This notebook embeds:

- All 15 ACT II probabilistic / causal / relational methods
- Source code for each `src/<module>.py`
- Full training scripts as markdown code blocks
- Mathematical derivations (first-principles)
- All plots and visualizations
- 5 ACT III pathway placeholders

Total sections: ~20 (15 methods + 5 pathways) **Expected PDF pages:** 200–300 **Execution time:** ~5–10 min (plots only; scripts are embedded non-executable)

Navigation

ACT II: Probabilistic & Causal Stack (15 methods)

1. Gaussian Process
2. Kalman Ladder
3. Particle Filter
4. Hidden Markov Model
5. Conformal Prediction
6. GenMatch Genetic Algorithm
7. MovieLens Twin
8. TVAE Synthetic Augmentation
9. LightGCN
10. Heterogeneous Attention Network
11. MC Dropout BNN
12. Hierarchical Bayesian ANOVA
13. IPW + AIPW Causal Estimation
14. Thompson Sampling Bandit
15. CVAE Conditional Generation

ACT III: Generative Pathways (5 placeholders)

A. Generic AnimateDiff B0. Motion LoRA (unaugmented) B1. Motion LoRA (GenMatch-augmented) B2. Motion LoRA (fully augmented) C. CogVideoX Alternative

---

1. Gaussian Process with RBF + Periodic + String Kernels

Intent: Posterior inference over Temilola's rating surface using an additive kernel combining RBF (content similarity), Periodic (date-watched seasonality), and String (title characters). Produces posterior mean ratings with pointwise uncertainty across 50K TMDB movies.

Mathematical Derivation

GP posterior via Cholesky

Given training pairs (X, y), kernel k, noise σ^2: $p(f_*|X, y, X_*) = \mathcal{N}(\mu_*, \Sigma_*)$ where $\mu_* = K_{*X}(K + \sigma^2 I)^{-1} y \, \Sigma_* = K_{**} - K_{*X}(K + \sigma^2 I)^{-1} K_{X*}$

Numerical stability: Cholesky $K + \sigma^2 I = LL^T$, solve $\alpha = L^{-T} L^{-1} y$ once. LML: $\log p(y|X) = -\frac{1}{2} y^T \alpha - \sum \log L_{ii} - \frac{n}{2} \log 2\pi$.

Mathematical Derivation

Kalman gain derivation

Linear-Gaussian state-space: $x_t = Fx_{t-1} + w_t,\ w_t \sim \mathcal{N}(0, Q)$
$y_t = Hx_t + v_t,\ v_t \sim \mathcal{N}(0, R)$

Posterior after observing y_t is Gaussian. Matching moments of $p(x_t|y_{1:t}) \propto p(y_t|x_t)p(x_t|y_{1:t-1})$ gives the update equations. The gain $K = PH^T(HPH^T + R)^{-1}$ minimises posterior MSE; see Murphy 2012 §18.3 for full derivation.

$x_t \leftarrow x_t + K(y_t - Hx_t)\ P_t \leftarrow (I - KH)P_t$

Visualizations

In [ ]:
```
from IPython.display import Image, display
display(Image('artifacts/plots/kalman_ladder.png'))
```

3. Bootstrap Particle Filter + Forward-Filter-Backward-Smoother (FFBSi)

Intent: Fully nonparametric, non-Gaussian sequential inference on rating dynamics. Uses sequential importance resampling and backward-smoothing to produce non-Gaussian posterior samples. Top rung of the state-space ladder: no linearity or Gaussianity assumptions.

Mathematical Derivation

UKF sigma-point weights (Merwe scaled)

For an n-dimensional state, $2n+1$ sigma points capture mean+covariance under nonlinear transforms to 3rd-order Taylor accuracy. Merwe's scaled set:

$\lambda = \alpha^2(n+\kappa) - n$, defaults $\alpha = 10^{-3}, \beta = 2, \kappa = 0$. Sigma points: $\chi_0 = x$, $\chi_i = x \pm (\sqrt{(n+\lambda)P})_i$. Weights: $W_0^{(m)} = \lambda/(n+\lambda)$ $W_0^{(c)} = \lambda/(n+\lambda) + (1-\alpha^2+\beta)$ $W_i^{(m)} = W_i^{(c)} = 1/(2(n+\lambda))$ for $i \geq 1$. $\beta = 2$ is optimal for Gaussian priors (incorporates prior knowledge of kurtosis).

Visualizations

In [ ]:
```
from IPython.display import Image, display
display(Image('artifacts/plots/pf_cloud.png'))
```

4. Hidden Markov Model (3-State Regimes)

Intent: Discrete latent regimes (Explorer, Critic, Comfort-Watcher) governing rating behavior. Trains a 3-state HMM via EM on chronological ratings and visualizes regime transitions. Captures non-stationary taste evolution as discrete mode-switching.

HMM forward-backward in log-space

Model

Hidden state $z_t \in \{1, \ldots, K\}$, discrete observation $x_t \in \{1, \ldots, B\}$.

Parameters:

- Transition matrix: $A_{ij} = P(z_t = j | z_{t-1} = i)$ (K × K)
- Emission matrix: $E_{ib} = P(x_t = b | z_t = i)$ (K × B)
- Initial distribution: $\pi_i = P(z_1 = i)$ (K)

Forward Algorithm

Definition: $\alpha_t(i) = P(x_{1:t}, z_t = i)$ (joint probability of observations and state)

Log-space recurrence:

$$\log \alpha_1(i) = \log \pi_i + \log E_{i,x_1}$$

$$\log \alpha_t(i) = \log E_{i,x_t} + \mathrm{logsumexp}_j(\log \alpha_{t-1}(j) + \log A_{ji})$$

where $\mathrm{logsumexp}_j(a_j) = \max_j(a_j) + \log \sum_j \exp(a_j - \max_k(a_k))$ for numerical stability.

Backward Algorithm

Definition: $\beta_t(i) = P(x_{t+1:T}|z_t = i)$ (likelihood of future observations given state)

Log-space recurrence:

$$\log \beta_T(i) = 0$$

$$\log \beta_t(i) = \text{logsumexp}_j(\log A_{ij} + \log E_{j,x_{t+1}} + \log \beta_{t+1}(j))$$

Likelihood

Total observation likelihood:

$$\log P(x_{1:T}) = \text{logsumexp}_i(\log \alpha_T(i))$$

This can also be computed via β_1 in initial frame (numerical validation).

Posterior State Occupancy

State posterior (filtering distribution):

$$\gamma_t(i) = P(z_t = i|x_{1:T}) = \frac{\alpha_t(i)\beta_t(i)}{P(x_{1:T})}$$

In log-space:

$$\log \gamma_t(i) = \log \alpha_t(i) + \log \beta_t(i) - \log P(x_{1:T})$$

State Transition Posterior

Joint state posterior:

$$\xi_t(i,j) = P(z_t = i, z_{t+1} = j|x_{1:T}) = \frac{\alpha_t(i)A_{ij}E_{j,x_{t+1}}\beta_{t+1}(j)}{P(x_{1:T})}$$

In log-space:

$$\log \xi_t(i,j) = \log \alpha_t(i) + \log A_{ij} + \log E_{j,x_{t+1}} + \log \beta_{t+1}(j) - \log P(x_{1:T})$$

Baum-Welch (EM) M-Step

Update parameters using expected counts:

Initial state distribution:

$$\pi_i \leftarrow \gamma_1(i)$$

Transition matrix:

$$A_{ij} \leftarrow \frac{\sum_{t=1}^{T-1} \xi_t(i,j)}{\sum_{t=1}^{T-1} \gamma_t(i)}$$

Emission matrix:

$$E_{ib} \leftarrow \frac{\sum_{t:x_t=b} \gamma_t(i)}{\sum_{t=1}^{T} \gamma_t(i)}$$

After each update, normalize to ensure distributions sum to 1.

Viterbi Algorithm (Most Likely Path)

Definition: $\delta_t(i) = \max_{z_{1:t-1}} P(z_{1:t} = (\ldots, i), x_{1:t})$ (max log-probability)

Recurrence:

$$\delta_1(i) = \log \pi_i + \log E_{i,x_1}$$

$$\delta_t(i) = \max_j(\delta_{t-1}(j) + \log A_{ji}) + \log E_{i,x_t}$$

Backpointer: $\psi_t(i) = \arg\max_j(\delta_{t-1}(j) + \log A_{ji})$

Backtrack: $z_T^* = \arg\max_i \delta_T(i)$, then $z_t^* = \psi_{t+1}(z_{t+1}^*)$

Numerical Stability Notes

- All computations performed in **log-space** to avoid underflow on long sequences
- Use $\mathrm{logsumexp}$ with max-subtraction trick for log-domain addition
- Clip small probabilities to 10^{-300} before taking logarithm
- All distributions (A, E, π) stored as normalized probabilities; convert to log only when needed

```

Mathematical Derivation

Split conformal prediction — marginal coverage guarantee

Setup. Data (X_i, Y_i) iid from P. Split into proper-train $\mathcal{D}_1$ and calibration $\mathcal{D}_2$ (size n). Fit any base regressor $\hat{f}$ on $\mathcal{D}_1$. Compute residual scores $R_i = |Y_i - \hat{f}(X_i)|$ for $i \in \mathcal{D}_2$.

Let $\hat{q} = R_{(\lceil (1-\alpha)(n+1) \rceil)}$, the $\lceil (1-\alpha)(n+1) \rceil$-th order statistic of the calibration residuals.

Prediction interval: $C(X_{n+1}) = [\hat{f}(X_{n+1}) - \hat{q},\ \hat{f}(X_{n+1}) + \hat{q}]$.

Theorem (Vovk, Shafer, Lei). For an exchangeable test point (X_{n+1}, Y_{n+1}):

$$\Pr(Y_{n+1} \in C(X_{n+1})) \geq 1 - \alpha.$$

Proof sketch. By exchangeability, the rank of R_{n+1} among $\{R_1, \ldots, R_{n+1}\}$ is uniform on $\{1, \ldots, n+1\}$. Hence $\Pr(R_{n+1} \leq \hat{q}) \geq \lceil (1-\alpha)(n+1) \rceil / (n+1) \geq 1 - \alpha$.

Guarantee is **distribution-free** (no assumption on $\hat{f}$ or P) and **marginal** (not conditional on X). Upper bound $1 - \alpha + 1/(n+1)$ holds when scores have no ties.

Mathematical Derivation

GenMatch GA fitness derivation

Problem. Observational data $X \in \mathbb{R}^{n \times d}$, binary treatment $T \in \{0,1\}^n$. Goal: match each treated unit to its nearest control unit so that — marginally across the d covariates — the matched treated/control distributions are statistically indistinguishable.

Distance. Weighted Mahalanobis with diagonal scaling:
$d_w(x, x') = \sqrt{(x - x')^T W^{1/2} \Sigma^{-1} W^{1/2} (x - x')}$, where Σ is the pooled covariance and $W = \mathrm{diag}(w)$ with $w \geq 0$.

Fitness. For weights w, let $M(w)$ be the matched-control assignment obtained by nearest-neighbour search under d_w. Define
$F(w) = \min_{j=1..d} \mathrm{KS\text{-}pvalue}\big(X_{T=1,j},\ X_{M(w),j}\big)$.

This is Sekhon & Diamond's "minimum p-value" criterion: the GA maximises the worst-covariate p-value, which forces balance across *all* covariates simultaneously rather than averaging.

Genetic algorithm. Real-valued chromosomes $w \in \mathbb{R}_+^d$:

- Tournament selection (k = 3)
- Uniform per-gene crossover: child = $\alpha a + (1-\alpha)b,\ \alpha \sim U(0,1)^d$
- Gaussian mutation: each gene mutates with probability p_m by $\mathcal{N}(0, \sigma_m)$, clipped at 0
- Elitism: top-e individuals pass through unchanged → guarantees $F_t^* \geq F_{t-1}^*$

Convergence intuition. Each generation the best-so-far fitness is monotone non-decreasing in expectation under elitism; in practice after 20–50 generations the GA settles near a weighting that balances all covariates simultaneously. The worst-covariate objective makes the matching robust to covariate miscalibration.

7. MovieLens Twin (Synthetic Augmentation via k-NN)

Intent: Locate Temilola's k-nearest neighbor in MovieLens 25M using content embeddings. Borrow that user's ratings as synthetic observations to expand the label set from N=162 to ~10K. Pillar 1 of data augmentation: real user as proxy for unobserved taste.

Training Script: `scripts/14_movielens_twin.py`

```
#!/usr/bin/env python3
"""
Task 1.7: MovieLens twin dataset generation.

Find top-K users in MovieLens whose rating patterns correlate with
Temilola's 324
real ratings, and borrow their full rating vectors to produce a
pseudo-rating
dataset of ≥50K rows that expands beyond the 82-movie catalog.

Uses numpy cosine-similarity (NOT lightfm, which is broken on
Python 3.12 macOS).

Mathematical Derivation

TVAE ELBO Derivation

Evidence Lower Bound (ELBO)

We seek to maximize the log-likelihood $\log p(x)$ of the data. Using the variational inference framework with an encoder distribution $q(z|x)$ and prior $p(z)$:

$$\log p(x) = \log \int p(x|z)p(z)dz$$

By introducing $q(z|x)$ and applying Jensen's inequality:

$$\log p(x) = \log \mathbb{E}_{z\sim q(z|x)} \left[\frac{p(x,z)}{q(z|x)} \right]$$

$$\geq \mathbb{E}_{z\sim q(z|x)} \left[\log \frac{p(x,z)}{q(z|x)} \right]$$

$$= \mathbb{E}_{z\sim q(z|x)} \left[\log p(x|z) \right] - \mathbb{E}_{z\sim q(z|x)} \left[\log \frac{q(z|x)}{p(z)} \right]$$

$$= \mathbb{E}_{z\sim q} \left[\log p(x|z) \right] - KL(q(z|x) \parallel p(z))$$

The right-hand side is the **Evidence Lower Bound (ELBO)**.

ELBO in Practice

1. Reconstruction Loss

Assuming a Gaussian decoder with variance 1:

$$\mathbb{E}_{z\sim q}\left[\log p(x|z)\right] \approx -\frac{1}{2N}\sum_{i=1}^{N}\|x_i - \mu_{\text{dec}}(z_i)\|^2$$

where $\mu_{\text{dec}}(z)$ is the decoder output (reconstruction). This is the **Mean Squared Error (MSE)** loss.

2. KL Divergence

With $q(z|x) = \mathcal{N}(z; \mu_{\text{enc}}(x), \sigma^2_{\text{enc}}(x)I)$ and prior $p(z) = \mathcal{N}(0, I)$:

$$KL(q(z|x) \parallel p(z)) = \frac{1}{2N}\sum_{i=1}^{N}\sum_{j=1}^{z_{\text{dim}}}\left[1 + \log\sigma^2_{ij} - \mu^2_{ij} - \sigma^2_{ij}\right]$$

We parameterize via $\log_{\text{var}} = \log(\sigma^2)$, so:

$$KL = \frac{1}{2N}\sum_{i,j}\left[1 + \log\text{var}_{ij} - \mu^2_{ij} - \exp(\log\text{var}_{ij})\right]$$

3. Total Loss

$$\text{ELBO} = \text{MSE}(x, \hat{x}) + \beta \cdot KL(q \parallel p)$$

where β is a weighting factor (often set to 1.0 or annealed during training).

Reparameterization Trick

To enable backpropagation through the sampling operation:

$$z = \mu(x) + \sigma(x) \odot \epsilon, \quad \epsilon \sim \mathcal{N}(0, I)$$

where $\odot$ is element-wise multiplication and $\sigma(x) = \exp(0.5\log\text{var}(x))$.

Implementation Notes

- **Encoder**: Maps $x \in \mathbb{R}^d \to (\mu, \log\text{var}) \in \mathbb{R}^{z_{\text{dim}}} \times \mathbb{R}^{z_{\text{dim}}}$
- **Decoder**: Maps $z \in \mathbb{R}^{z_{\text{dim}}} \to \hat{x} \in \mathbb{R}^d$ (reconstruction)
- **Loss computation**: Minimizing negative ELBO
- **KL annealing** (optional): Gradually increase β from 0 to 1 during training to avoid posterior collapse

display(Image('artifacts/plots/tvae_overlap.png'))
```

9. LightGCN (Graph Collaborative Filtering)

Intent: Bipartite graph neural network on (user, movie) edges. Message-passing propagation learns user/movie embeddings capturing collaborative signal. Feeds into downstream GP, Kalman, or CVAE for relational grounding.

Source Modules

- `src/lightgcn.py`

File: `src/lightgcn.py`

```
#!/usr/bin/env python3
"""
LightGCN: From-scratch 4-layer Graph Convolutional Network for
recommendation.

Reference: https://arxiv.org/abs/2002.02126 (He et al., 2020)

Architecture:
- Input: user & item embeddings E_u ∈ ℝ^(n_u × d), E_v ∈ ℝ^(n_v ×
d)
- Bipartite adjacency: A (user-item interactions, symmetrically
normalized)
- Propagation: E^(k+1) = A_hat @ E^(k), no weights, no activations
- Output: mean-pool over K+1 layers (0, 1, ..., K)
- Scoring: s(u, v) = <E_u_final, E_v_final>
- Loss: BPR (Bayesian Personalized Ranking)

Key insight: Graph message passing without learnable weights or
nonlinearities,
only structural signal from the bipartite graph.

Mathematical Derivation

Derivation: LightGCN Propagation

Background

LightGCN (He et al., 2020) is a simplified Graph Convolutional Network for recommendation. It removes nonlinearities and learnable feature transformations that complicate GNNs, keeping only the graph structure's implicit collaborative signal.

Notation

- n_u = number of users
- n_v = number of items (variants call this "products" or "vertices")
- d = embedding dimension (typically 64)
- K = number of propagation layers (typically 4)
- $\mathcal{G} = (\mathcal{U} \cup \mathcal{V}, \mathcal{E})$ = bipartite user-item interaction graph
- $A \in \mathbb{R}^{(n_u+n_v)\times(n_u+n_v)}$ = adjacency matrix (block form below)
- $\tilde{A} = D^{-1/2}AD^{-1/2}$ = symmetrically normalized adjacency
- $E^{(k)} \in \mathbb{R}^{(n_u+n_v)\times d}$ = stacked embeddings at layer k

Adjacency Structure

Stack users and items into a single vector:

$$\begin{bmatrix} E_u^{(k)} \\ E_v^{(k)} \end{bmatrix}$$

where $E_u^{(k)} \in \mathbb{R}^{n_u \times d}$ and $E_v^{(k)} \in \mathbb{R}^{n_v \times d}$.

The bipartite adjacency is:

$$A = \begin{bmatrix} 0 & A_{uv} \\ A_{vu} & 0 \end{bmatrix}$$

where A_{uv} is the $n_u \times n_v$ user-item interaction matrix (1 if $(u, v) \in \mathcal{E}$, 0 else). By symmetry, $A_{vu} = A_{uv}^\top$.

Degree matrix: $D = \mathrm{diag}(d_1, d_2, \ldots, d_{n_u+n_v})$ where $d_i = \sum_j A_{ij}$.

Normalization: $\tilde{A} = D^{-1/2} A D^{-1/2}$

Each edge (i, j) is re-weighted:

$$\tilde{A}_{ij} = \frac{A_{ij}}{\sqrt{d_i d_j}}$$

Why? This normalization is the symmetric form of Laplacian normalization from spectral graph theory. It:

1. Accounts for graph irregularity (high-degree nodes would dominate without scaling)
2. Stabilizes eigenvalues near $\lambda \in [-1, 1]$, aiding iterative propagation
3. Preserves the spectral properties needed for effective message-passing

Propagation: $E^{(k+1)} = \tilde{A} E^{(k)}$

Message-passing without weights or nonlinearities:

$$E^{(k+1)} = \tilde{A} E^{(k)}$$

Expanding for user embedding at layer $k + 1$:

$$E_u^{(k+1)} = \tilde{A}_{u,:} E^{(k)} = \sum_{i=1}^{n_u+n_v} \tilde{A}_{u,i} e_i^{(k)}$$

This decomposes:

- User-to-user: $\sum_{u' \neq u} \tilde{A}_{u,u'} e_{u'}^{(k)}$ (almost always 0 for bipartite)
- User-to-item: $\sum_{v=1}^{n_v} \tilde{A}_{u,n_u+v} e_v^{(k)}$ (nonzero from interactions)

Specifically, if user u interacted with items $v_1, \ldots, v_m$:

$$\boxed{E_u^{(k+1)} = \sum_{j=1}^{m} \frac{1}{\sqrt{d_u d_{n_u+v_j}}} E_v^{(k)}_j}$$

i.e., average the embeddings of interacted items, scaled by the inverse-squared-degree factor.

Final Embedding: Mean Pooling

After K propagation steps, we have embeddings at layers $0, 1, \ldots, K$. The final embedding averages all layers:

$$E_u^* = \frac{1}{K+1} \sum_{k=0}^{K} E_u^{(k)}$$

Intuition: Early layers ($k = 0, 1$) are local neighborhoods (1-hop, 2-hop collaborators). Later layers ($k = 3, 4$) aggregate further out. Mean-pooling captures multi-hop structure.

Scoring and Loss

Scoring: Inner product of final embeddings:

$$\hat{s}(u, v) = E_u^* \cdot E_v^*$$

BPR Loss: For each triplet (user u, positive item v^+, negative item v^-):

$$L = -\log(\sigma(\hat{s}(u, v^+) - \hat{s}(u, v^-))) + \lambda \left(\|E_u^*\|^2 + \|E_{v^+}^*\|^2 + \|E_{v^-}^*\|^2 \right)$$

where:

- $\sigma(x) = \frac{1}{1+e^{-x}}$ is the sigmoid
- The first term is the ranking loss: maximize gap between positive and negative
- The second term is L_2 regularization ($\lambda \approx 10^{-4}$)

Key Insight: No Learnable Parameters

Unlike standard GCN, LightGCN has **no weight matrices** on edges or nodes. All learnable parameters are the initial embeddings $E_u^{(0)}, E_v^{(0)}$. The graph structure itself (via $\tilde{A}$) drives learning—purely relational.

This gives:

- Simplicity: fewer parameters ↔ less overfitting
- Efficiency: only matrix-vector multiplications (no dense weights)

- Interpretability: collaborative signal is explicit (neighborhood averaging)

Visualizations

In [ ]:
```
from IPython.display import Image, display
display(Image('artifacts/plots/lightgcn_training.png'))
```

10. Heterogeneous Attention Network (HAN)

Intent: Heterogeneous graph neural network on (user, movie, actor, director, genre) nodes. Type-specific attention learns embeddings respecting domain structure. Captures indirect collaborative signal (who else liked movies with actor X?).

Source Modules

- `src/han.py`

File: `src/han.py`

```

Mathematical Derivation

HAN (Heterogeneous Attention Network) Derivation

Overview

HAN is a graph neural network designed for heterogeneous graphs (multiple node types and edge types). We apply it to the movie-genre graph to learn movie representations that capture both explicit features and co-occurrence patterns via genres.

Graph Schema

Node Types:

- `movie` (82 nodes): movies with features [year, runtime, vote_average, n_genres]
- `genre` (16 nodes): genre categories

Edge Types:

- `movie → genre`: movie has this genre
- `genre → movie`: reverse
- `movie → genre → movie` (meta-path): two movies share a genre

Meta-Paths

We consider two meta-paths for aggregating information:

1. **MGM (movie-genre-movie)**: captures co-genre relations — movies that share genres influence each other
2. **M (self)**: captures intrinsic movie features via self-attention

Node-Level Attention

For each meta-path Φ, we compute attention-based aggregation over neighbors.

Input: node features $h \in \mathbb{R}^{n \times d_{in}}$, adjacency matrix $A_\Phi \in \{0,1\}^{n \times n}$

Step 1: Transform features

$$\tilde{h} = W_\Phi h \quad \text{where } W_\Phi \in \mathbb{R}^{d_{in} \times h}$$

Step 2: Compute attention logits For each pair (i, j):

$$e_{ij}^\Phi = \text{LeakyReLU}\left(a_\Phi^T [\tilde{h}_i || \tilde{h}_j]\right)$$

where $a_\Phi \in \mathbb{R}^{2h}$ is a learnable attention vector, and $||$ denotes concatenation.

In matrix form (via broadcasting):

$$E^\Phi = \text{LeakyReLU}\left((W_\Phi h) a_\Phi^T + a_\Phi (W_\Phi h)^T\right) \quad \text{or simpler: } E_{ij}^\Phi = \text{LeakyReLU}(a_\Phi^T(\tilde{h}_i$$

Step 3: Mask and normalize

$$\tilde{e}_{ij}^\Phi = \begin{cases} e_{ij}^\Phi & \text{if } A_{ij}^\Phi = 1 \\ -\infty & \text{otherwise} \end{cases}$$

$$\alpha_{ij}^\Phi = \frac{\exp(\tilde{e}_{ij}^\Phi)}{\sum_k \exp(\tilde{e}_{ik}^\Phi)}$$

Step 4: Aggregate

$$z_i^\Phi = \sigma\left(\sum_j \alpha_{ij}^\Phi \tilde{h}_j\right) = \text{sigmoid}\left(\alpha_i^\Phi \tilde{H}\right)$$

where σ is sigmoid to ensure stability.

Output: $Z^\Phi \in \mathbb{R}^{n \times h}$ — aggregated node embeddings for meta-path Φ

Semantic-Level Attention

After computing node embeddings for each meta-path, we combine them via attention over meta-paths.

Input: List of embeddings $\{Z^\Phi : \Phi \in \text{meta-paths}\}$

Step 1: Compute meta-path importance For each meta-path Φ:

$$w^\Phi = \frac{1}{n} \sum_{i=1}^{n} \left(q^T \tanh(W_{\text{sem}} z_i^\Phi + b) \right)$$

where:

- $q \in \mathbb{R}^h$ is a learnable query vector
- $W_{\text{sem}} \in \mathbb{R}^{h \times h}$ is a semantic projection matrix
- $b \in \mathbb{R}^h$ is a bias term
- The mean is taken over all nodes (or can be a single scalar per path)

Step 2: Normalize over meta-paths

$$\beta^\Phi = \frac{\exp(w^\Phi)}{\sum_{\Phi'} \exp(w^{\Phi'})}$$

The vector $\beta = [\beta^{\Phi_1}, \beta^{\Phi_2}, \ldots]$ sums to 1 and reflects the importance of each meta-path.

Step 3: Aggregate over meta-paths

$$z_i = \sum_\Phi \beta^\Phi z_i^\Phi$$

Each movie's final embedding is a weighted sum of its meta-path-specific embeddings.

Intuition

- **Node-level attention:** allows the model to focus on relevant neighbors within each meta-path (e.g., in the MGM path, attend more to co-genre movies that are "similar").
- **Semantic-level attention:** learns which meta-paths are more important for the overall task. If the MGM path is informative, β will weight it higher.

Implementation Details

- **Hidden dim:** $h = 32$

- **Attention heads:** 1 (single-head; multi-head is optional)
- **Activation:** LeakyReLU with negative slope 0.2, sigmoid for aggregation
- **Number of meta-paths:** 2 (MGM + M)
- **Classification:** linear head on final embeddings → 2 classes (binary classification)

Loss and Training

- **Loss:** Binary cross-entropy (or 2-class cross-entropy)
- **Optimizer:** Adam, lr=0.001
- **Epochs:** 100
- **Train/val split:** 70/30 stratified by label

Results

On the 82-movie graph with 79 labeled examples:

Metric	Value
Train Accuracy	0.5273
Val Accuracy	0.5000
β (MGM)	0.533
β (M)	0.467

The modest accuracy reflects the challenge of predicting fine-grained ratings from limited features and a small labeled set. The semantic attention weights indicate that the MGM meta-path (co-genre relations) is slightly more informative (53.3%) than self-attention (46.7%), suggesting that knowing which genres a movie has is useful for predicting whether a user will rate it highly.

Mathematical Derivation

MC Dropout as Variational Inference in Deep GPs

Connection (Gal & Ghahramani 2016)

A standard neural network with **dropout kept active at test time** approximates Bayesian inference in a deep Gaussian Process.

Key Insight

When we apply dropout with mask $\mathbf{M}_t$ (where $M_{ij} \sim \text{Bernoulli}(1-p)$) to weight matrices $\mathbf{W}$, we are sampling from a distribution over weight configurations:

$$\mathbf{W}_t = \text{diag}(\mathbf{M}_t)\mathbf{W}$$

Running T forward passes with different dropout masks gives us T stochastic samples from the posterior predictive distribution.

Predictive Distribution

The posterior predictive distribution over outputs given input $\mathbf{x}$ is approximated by:

$$p(y|\mathbf{x}) \approx \frac{1}{T}\sum_{t=1}^{T} f(\mathbf{x}; \mathbf{W}_t)$$

where $\mathbf{W}_t$ is the weight matrix with dropout mask applied.

Mean and Variance Estimates

From T forward passes $\{y_t\}_{t=1}^{T}$:

Predictive mean:

$$\mu(\mathbf{x}) = \frac{1}{T}\sum_{t=1}^{T} f(\mathbf{x}; \mathbf{W}_t)$$

Predictive variance (sample-based, ignoring aleatoric term):

$$\sigma^2(\mathbf{x}) = \frac{1}{T}\sum_{t=1}^{T} f(\mathbf{x}; \mathbf{W}_t)^2 - \mu(\mathbf{x})^2$$

This variance estimate captures **epistemic uncertainty** (model uncertainty) due to the distribution over network weights.

Why It Works

1. **Variational Approximation:** Dropout induces a variational distribution $q(\mathbf{W})$ over weights that differs from the prior $p(\mathbf{W})$.

2. **ELBO Lower Bound:** Training with dropout-regularized loss minimizes a variational upper bound on the classification/regression error, which is equivalent to maximizing

the ELBO (Evidence Lower Bound) in a Bayesian interpretation.

3. **Posterior Sampling:** Each stochastic forward pass samples from the approximate posterior distribution $q(\mathbf{y}|\mathbf{x})$.

Advantages

- **No retraining required:** Use an already-trained network; just keep dropout active.
- **Computational efficiency:** T forward passes is cheap compared to methods like MCMC.
- **Scalability:** Works on large deep networks (unlike many exact Bayesian methods).

Limitations

- Provides only an **approximation** to true Bayesian inference.
- The uncertainty estimates depend heavily on the dropout rate and training procedure.
- Does not distinguish between aleatoric (data) and epistemic (model) uncertainty explicitly.

Application to Movie Ratings

In Task 1.11, we use MC Dropout to estimate predictive uncertainty in a 2-layer neural network predicting Temilola's movie ratings from features (year, runtime, TMDB vote, genres, modality).

- **Model:** Simple MLP with dropout at $p = 0.2$ between layers.
- **Inference:** $T = 50$ forward passes on each test sample.
- **Uncertainty:** Standard deviation across the 50 predictions indicates which movie-modality pairs the model is most unsure about.
- **Interpretation:** High uncertainty could indicate:
  - The sample is far from training data.
  - Multiple plausible predictions exist (multimodal posterior).
  - The rating may be genuinely ambiguous for that movie/modality combination.

Visualizations

In [ ]:
```
from IPython.display import Image, display
display(Image('artifacts/plots/bnn_mcd_uncertainty.png'))
```

12. Hierarchical Bayesian ANOVA

Intent: PyMC hierarchical ANOVA decomposing variance into [genre, director, actor, release_year] main effects + interactions. Posterior credible intervals on effect sizes reveal which attributes most strongly influence Temilola's taste. Interpretability anchor complementing black-box methods.

Mathematical Derivation

Derivation 14: Bayesian Hierarchical One-Way ANOVA (PyMC)

Task 1.12 Date: 2026-04-23 **Purpose**: Estimate how much of the variance in Temilola's 324 movie ratings is explained by **modality** (all / metadata / poster / synopsis) vs. movie-level variation.

---

1. Generative Model

We model the observed ratings y_{ij} (rating for movie i under modality j) as a hierarchical structure:

$$
\begin{aligned}
\mu &\sim \mathcal{N}(3.5, 1.5) \quad \text{(grand mean, rating scale 1--5)} && (1)\\
\sigma_{\text{modality}} &\sim \text{HalfNormal}(0.5) \quad \text{(between-modality SD)} && (2)\\
a_m &\sim \mathcal{N}(0, \sigma_{\text{modality}}), \quad m \in \{0, 1, 2, 3\} \quad \text{(modality offsets)} && (3)\\
\sigma_{\text{movie}} &\sim \text{HalfNormal}(0.5) \quad \text{(between-movie SD)} && (4)\\
b_i &\sim \mathcal{N}(0, \sigma_{\text{movie}}), \quad i \in \{1, \ldots, 81\} \quad \text{(movie effects)} && (5)\\
\sigma_{\text{obs}} &\sim \text{HalfNormal}(0.5) \quad \text{(observation noise)} && (6)\\
y_{ij} &\sim \mathcal{N}(\mu + a_{m(j)} + b_i, \sigma_{\text{obs}}) && (7)
\end{aligned}
$$

Interpretation

- μ: Grand mean rating (expected rating when all effects are zero, after centering).
- a_m: Offset for modality m (how much does modality shift ratings relative to grand mean?).
- b_i: Per-movie random effect (movies vary in baseline rating quality).
- σ_{modality}: Controls the magnitude of modality-to-modality variation.
- σ_{movie}: Controls the magnitude of movie-to-movie variation.
- σ_{obs}: Unexplained noise (residual variance).

---

2. Why Bayesian Hierarchical (Partial Pooling)?

Classic Fixed-Effects ANOVA Problem

If we estimated modality effects separately (fixed-effects ANOVA):

- Each modality mean gets a point estimate.
- Small sample groups are unstable (high variance).
- No borrowing of strength across modalities.

Hierarchical Solution (Partial Pooling)

By placing $a_m \sim \mathcal{N}(0, \sigma_{\text{modality}})$:

- **If** modalities are similar (small σ_{modality}), all estimates shrink toward 0.
- **If** modalities are different (large σ_{modality}), estimates are less pulled.
- The data *learns* σ_{modality} from the ensemble of modality means.
- Smaller groups are automatically regularized; larger groups less so.

Benefit: Stable, interpretable estimates that account for uncertainty in the group-level variance.

---

3. Non-Centered Parameterization

We use a **non-centered** (or **hierarchical centered**) parameterization:

$$a_m = \sigma_{\text{modality}} \cdot a_m^{\text{raw}} \quad \text{where} \quad a_m^{\text{raw}} \sim \mathcal{N}(0, 1) \tag{8}$$
$$b_i = \sigma_{\text{movie}} \cdot b_i^{\text{raw}} \quad \text{where} \quad b_i^{\text{raw}} \sim \mathcal{N}(0, 1) \tag{9}$$

Why Non-Centered?

The centered parameterization

$$a_m \sim \mathcal{N}(0, \sigma_{\text{modality}})$$

creates **funnel geometry** in the posterior: when σ_{modality} is small, the individual a_m are tightly constrained, causing high correlations and slow mixing in NUTS.

The non-centered form decorrelates the hierarchical parameters, making NUTS sampler more efficient:

- a_m^{raw} has a fixed $\mathcal{N}(0, 1)$ prior (no funnel).
- a_m is determined by σ_{modality} and a_m^{raw}.
- The sampler can update the variance parameter and the raw parameters more independently.

---

4. Prior Choices

$\mu \sim \mathcal{N}(3.5, 1.5)$

- **Center**: 3.5 is the midpoint of the 1--5 rating scale.
- **SD**: 1.5 allows reasonable spread while staying on-scale.

$\sigma_{\text{modality}}, \sigma_{\text{movie}}, \sigma_{\text{obs}} \sim \text{HalfNormal}(0.5)$

- **HalfNormal**: Non-negative support (variance must be ≥ 0).
- **Scale 0.5**: For a 1--5 scale, $\sigma \approx 2$ is plausible maximum. HalfNormal(0.5) puts ~95% of probability below 1, accommodating realistic variation while strongly penalizing large variances.
- **Weakly informative**: Does not impose a hard upper bound, but gently regularizes against unrealistic values.

---

5. Data & Encoding

Input

- **File**: `data/modality_ratings.jsonl`
- **Rows**: 324 (Temilola's ratings)
- **Columns**: `tmdb_id, rating, modality` (plus metadata joined from `movies_meta.json`)

Encoding

```
# Modality → integer
modality_map = {'all': 0, 'metadata': 1, 'poster': 2, 'synopsis':
3}

# TMDB ID → movie index (0 ... 80)
# 81 unique movies across the 324 ratings
```

---

6. Inference

Sampling Strategy

- **Algorithm**: NUTS (No-U-Turn Sampler) with dual averaging.
- **Chains**: 2 chains.
- **Iterations per chain**: 1000 tune + 1000 draw = 2000 total.
- **Target acceptance**: 0.95.
- **Total samples**: 2 × 1000 = 2000 post-warmup draws.

Convergence Diagnostics

- $\hat{R}$ **(Gelman-Rubin Statistic)**: Should be < 1.01.
  - Compares within-chain and between-chain variance.
  - $\hat{R} \approx 1.0$ → chains are mixing well.
- **Effective Sample Size (ESS)**: Accounts for autocorrelation; should be >> 400 for reliable estimates.
- **Divergences**: Gradients that flip sign, indicating sampler trouble. 0 is ideal; <10 is acceptable.

---

7. Results Interpretation

Posterior Estimates

Each parameter's posterior is summarized by:

- **Mean**: Point estimate.

- **SD**: Posterior standard deviation.
- **94% HDI**: Highest Density Interval (Bayesian credible interval).

Key Questions Answered

1. **How much does modality matter?** Compare σ_{modality} (modality variance) to σ_{movie} (movie variance):
   - If $\sigma_{\text{modality}} \ll \sigma_{\text{movie}}$, then movies matter far more than modality.
   - If σ_{modality} is comparable, modality is a significant factor.
2. **Which modality is "best"?** Look at the posterior offsets a_m:
   - Positive → ratings higher than grand mean for that modality.
   - Negative → ratings lower.
   - If all 94% HDIs overlap zero, modality effects are negligible.
3. **How much noise?** σ_{obs} is the residual SD unexplained by the model.

---

8. Variance Decomposition

Total variance in ratings can be decomposed as:

$$\text{Var}(y) \approx \sigma^2_{\text{modality}} + \sigma^2_{\text{movie}} + \sigma^2_{\text{obs}}$$

(Approximate because the effects are additive on the mean, not the variance.)

Interpreting the plot:

- **Tall σ_{movie} bar**: Movies (narrative quality, genre, etc.) drive most variation.
- **Tall σ_{modality} bar**: Modality (visual vs. textual cues) is a major factor.
- **Tall σ_{obs} bar**: Residual noise dominates; model does not fit well.

---

9. Assumptions & Limitations

1. **Gaussian likelihood**: Assumes ratings are approximately normally distributed. For bounded ordinal data, a more robust approach (e.g., ordinal logit) could be explored.

2. **Additive effects**: Modality and movie effects are added linearly. No interaction terms (e.g., "Does modality X work especially well for movie Y?").

3. **Homoscedastic**: All observations have the same noise SD σ_{obs}. Could relax with group-level heteroskedasticity.

4. **2 chains**: The current run uses 2 chains. Best practice is 4+ chains for robust $\hat{R}$ diagnostics. With 2 chains, rely on ESS and visual inspection.

---

Appendix: Code Snippet (Non-Centered)

```
with pm.Model() as model:
    mu = pm.Normal('mu', mu=3.5, sigma=1.5)
    sigma_modality = pm.HalfNormal('sigma_modality', sigma=0.5)
    sigma_movie = pm.HalfNormal('sigma_movie', sigma=0.5)
    sigma_obs = pm.HalfNormal('sigma_obs', sigma=0.5)

    # Non-centered: raw parameters
    a_m_raw = pm.Normal('a_m_raw', mu=0, sigma=1.0, shape=4)
    a_m = pm.Deterministic('a_m', sigma_modality * a_m_raw)

    b_i_raw = pm.Normal('b_i_raw', mu=0, sigma=1.0, shape=81)
    b_i = pm.Deterministic('b_i', sigma_movie * b_i_raw)

    # Likelihood
    mu_ij = mu + a_m[modality_idx] + b_i[movie_idx]
    y = pm.Normal('y', mu=mu_ij, sigma=sigma_obs, observed=ratings)

    idata = pm.sample(draws=1000, tune=1000, chains=2,
target_accept=0.95)
```

This ensures efficient sampling on hierarchical structure while remaining interpretable.

13. Inverse Probability Weighting (IPW) + Augmented IPW (AIPW)

Intent: Doubly-robust causal estimators for counterfactual rating under hypothetical modality conditions. IPW (single-model) + AIPW (nuisance-debiased) estimate effect of "seeing poster" vs "seeing synopsis" on rating. Pairs with GenMatch for comprehensive debiasing.

Source Modules

Mathematical Derivation

Derivation: IPW and AIPW Estimators for Average Treatment Effect

Potential Outcomes Framework

Setup: Binary treatment $T \in \{0, 1\}$, outcome $Y \in \mathbb{R}$, covariates $X \in \mathbb{R}^p$.

For each unit i, define potential outcomes:

- $Y_i(1)$ = outcome under treatment
- $Y_i(0)$ = outcome under control

Observed outcome: $Y_i = T_i Y_i(1) + (1 - T_i) Y_i(0)$

Parameter of Interest

Average Treatment Effect (ATE):

$$\tau = \mathbb{E}[Y(1) - Y(0)]$$

Key Assumption: Unconfoundedness (Conditional Independence)

Treatment assignment is independent of potential outcomes given observed covariates:

$$T \perp\!\!\!\perp (Y(0), Y(1)) \mid X$$

This implies:

- **Propensity score:** $e(x) = P(T = 1 \mid X = x)$ fully captures confounding
- **No hidden bias:** All confounders are measured in X

IPW Estimator (Inverse Probability Weighting)

Derivation

Under unconfoundedness, we can reweight by inverse propensity scores to create pseudo-populations where treatment is independent of X:

$$\tau_{IPW} = \mathbb{E}\left[\frac{T \cdot Y}{e(X)}\right] - \mathbb{E}\left[\frac{(1-T) \cdot Y}{1 - e(X)}\right] \tag{10}$$

$$= \mathbb{E}[Y(1)] - \mathbb{E}[Y(0)] \tag{11}$$

Intuition:

- Units with $T = 1$ are weighted by $1/e(X)$ (more weight if rare to be treated given X)
- Units with $T = 0$ are weighted by $1/(1 - e(X))$ (more weight if rare to be untreated given X)
- Reweighting balances the covariate distributions between groups

Sample Estimator

$$\hat{\tau}_{IPW} = \frac{1}{n}\sum_{i=1}^{n}\left[\frac{T_i Y_i}{\hat{e}(X_i)} - \frac{(1-T_i)Y_i}{1-\hat{e}(X_i)}\right]$$

where $\hat{e}(X_i)$ is the estimated propensity score.

Variance

IPW is sensitive to:

- **Positivity violation:** If $e(x) \approx 0$ or $e(x) \approx 1$, weights explode
- **Propensity misspecification:** If logistic regression is misspecified

AIPW Estimator (Augmented IPW, Doubly Robust)

Motivation

AIPW adds an outcome model $\mu_t(x) = \mathbb{E}[Y|T=t, X=x]$ to reduce variance:

Key property: Consistent if *either* the propensity model OR outcome model is correct (not both required).

Derivation

Define residuals:

$$R_t(x) = Y - \mu_t(X)$$

Under unconfoundedness:

$$\begin{aligned} \tau &= \mathbb{E}[\mu_1(X) - \mu_0(X)] && (12) \\ &\quad + \mathbb{E}[T \cdot R_1(X)/e(X)] - \mathbb{E}[(1-T)\cdot R_0(X)/(1-e(X))] && (13) \end{aligned}$$

The first term uses the outcome model directly. The second/third terms use residual weighting (IPW on residuals).

Sample Estimator

$$\hat{\tau}_{AIPW} = \frac{1}{n}\sum_{i=1}^{n}\left[\hat{\mu}_1(X_i) - \hat{\mu}_0(X_i) + \frac{T_i(\hat{Y}_i - \hat{\mu}_1(X_i))}{\hat{e}(X_i)} - \frac{(1-T_i)(\hat{Y}_i - \hat{\mu}_0(X_i))}{1-\hat{e}(X_i)}\right]$$

Double Robustness Property

Theorem: If $\hat{e}(x) \to e(x)$ or $\hat{\mu}_t(x) \to \mu_t(x)$ (or both), then $\hat{\tau}_{AIPW} \to \tau$.

Proof sketch: The IPW residual terms vanish asymptotically if either model is correct.

Efficiency

When the outcome model is well-specified:

$$\mathrm{Var}(\hat{\tau}_{AIPW}) \leq \mathrm{Var}(\hat{\tau}_{IPW})$$

AIPW gains efficiency from outcome information while maintaining robustness to propensity misspecification.

Implementation Details

Propensity Score Estimation

Fit logistic regression via gradient descent on negative log-likelihood:

$$\ell(w, b) = -\frac{1}{n} \sum_i [T_i \log(\sigma(x_i^\top w + b)) + (1 - T_i) \log(1 - \sigma(x_i^\top w + b))]$$

where $\sigma(z) = 1/(1 + e^{-z})$ is the sigmoid.

Gradient step: $w \leftarrow w - \alpha \nabla_w \ell$

Numerical stability:

- Clip logits to $[-500, 500]$ to prevent overflow
- Clip propensity scores to $[0.01, 0.99]$ for IPW to avoid extreme weights

Outcome Model Estimation

Fit two separate ridge-regularized OLS models:

$$\hat{\mu}_t(x) = \arg\min_w \left\| Y - Xw \|_2^2 + \lambda \| w \|_2^2 \right\|$$

solved via normal equations with $\lambda = 10^{-3}$.

Interpretation: Real Data Results

On Temilola's 324 movie ratings comparing synopsis vs metadata presentation:

Sample: 162 observations (81 synopsis, 81 metadata)
Outcome: Rating (0–10)
Covariates: Year, runtime, vote average, # genres (standardized)

Key finding:

- Naive difference in means: 0.006 points
- IPW ATE: 0.004 ± 0.406 [95% CI: -0.77, 0.80]

- AIPW ATE: 0.017 ± 0.112 [95% CI: -0.20, 0.23]

Interpretation: No significant causal effect detected. The synopsis modality vs metadata modality does not substantially affect ratings after adjusting for movie characteristics.

Overlap: Perfect overlap detected (propensity scores all ~0.5), suggesting treatment is well-balanced and no extrapolation required.

Mathematical Derivation

Task 1.14: Thompson Sampling on Gaussian Process

Motivation

Thompson Sampling is a Bayesian approach to the exploration-exploitation trade-off in multi-armed bandits. The key insight is **optimism in the face of uncertainty**: at each round, sample from your *posterior* belief about arm rewards, then act greedily on the sample.

Setting

- **Arms**: 39 movies (pool) with unknown rewards
- **Reward**: Temilola's true mean rating for each movie
- **Observations**: Started with 20 "seed" movies already rated, added new arms via bandit pulls
- **Features**: Per-movie features (year, runtime, vote_average, n_genres) — z-scored
- **Posterior**: Gaussian Process trained on observations

Thompson Sampling Algorithm

At round t:

1. **Sample from posterior**: Draw a joint sample $f \sim N(\mu_t, \Sigma_t)$ where:
    - $\mu_t(x) = \mathbb{E}[\text{reward}(x)|\text{data}_t]$ (GP posterior mean)
    - $\Sigma_t(x, x') = \text{Cov}[\text{reward}(x), \text{reward}(x')|\text{data}_t]$ (GP posterior covariance)
    - The sample is **joint** over all 39 arms, not independent per-arm
    - Use Cholesky decomposition: $LL^\top = \Sigma_t + \epsilon I$, then $f = \mu_t + Lz$ where $z \sim N(0, I)$
2. **Greedy selection**: Pick $a^* = \arg\max_i f[i]$

3. **Observe reward**: Get true reward $y = y_{a^*}$ (look up from ground truth)
4. **Update training set**: Add (x_{a^*}, y_{a^*}) to observations
5. **Refit GP**: Recompute μ_t, Σ_t on enlarged dataset
6. **Compute regret**: $r_t = \max_i y_i - y_{a^*}$ (instant regret), accumulate to cumulative regret

Why This Works

The posterior distribution captures **uncertainty** about each arm:

- Arms with few observations → high posterior variance → wider confidence intervals
- Arms consistent with the data → low posterior variance → confident predictions

By sampling from the posterior and acting greedily, Thompson sampling naturally **explores** high-variance (uncertain) arms and **exploits** low-variance (confident) high-mean arms.

Formally, this balances exploration-exploitation without explicit ϵ schedules:

$$\Pr[\text{sample arm} \mid \text{data}] \approx \Pr[\text{arm is optimal} \mid \text{data}]$$

Regret Bound (Sketch)

Under standard assumptions (sub-Gaussian rewards, bounded feature norms), Thompson sampling achieves:

$$\mathbb{E}[R_T] = O(\sqrt{dT \log T})$$

where d is feature dimension and T is number of rounds. This is near-optimal (matches lower bounds up to log factors).

Implementation Notes

- **Cholesky stability**: Add jitter (10^{-6} to diagonal) to avoid numerical issues
- **GP refitting**: Refit after each observation (feasible for 39 arms × 20 rounds = 780 GPs)
- **Kernel choice**: RBF with length=1.0, variance=1.0; noise=0.1 on training covariance
- **Joint vs independent**: Critical that we sample from the **joint** posterior, not per-arm. This encodes correlation structure learned by the GP

Results on 82 Movies

Experiment:

- 59 movies with complete features (year, runtime, vote_average, n_genres)
- 20 random seed observations
- 39 bandit arms
- 20 rounds, averaged over 10 random seeds

Performance:

- Thompson cumulative regret: **3.99 ± 1.10**
- Random baseline regret: **17.42 ± 1.68**
- **Advantage**: 13.42 regret reduction (77% improvement)

Top chosen arms (across all seeds):

1. Arm 16: 8.675 rating (pulled 169/200 times = dominant arm)
2. Arm 0: 8.300 rating (pulled 12 times)
3. Arm 14: 7.275 rating (pulled 6 times)

Arm 16 is the true max in the pool → Thompson quickly identified and exploited it. The steep curve vs random shows strong early learning.

Extensions

1. **Contextual Thompson**: If new movies arrive without ratings, use features to initialize prior
2. **Batch parallel**: Sample multiple Thompson arms, run in parallel, aggregate posterior
3. **Hyperparameter tuning**: Optimize GP kernel hyperparameters on held-out split
4. **Utility functions**: Swap reward for a non-linear utility (e.g., log-rating)

15. Conditional Variational Autoencoder (CVAE)

Intent: Generative model p(features | Temilola's taste centroid). Learns to synthesize "ideal" movie features matching latent taste vector. Feeds into ACT III: sample from CVAE → condition diffusion models → generate trailer.

Source Modules

- `src/cvae.py`

File: `src/cvae.py`

```python
"""
Conditional Variational Autoencoder (from-scratch PyTorch
implementation).

A 2-layer encoder/decoder with Gaussian latent variable and ELBO
loss.
Both encoder and decoder are conditioned on a discrete class label.

Architecture:
  - Conditional encoder: [x; c_onehot] → MLP → (μ, log_var in
R^z_dim)
  - Reparameterize: z = μ + σ ∗ ε, where σ = exp(0.5 ∗ log_var), ε
~ N(0, I)
  - Conditional decoder: [z; c_onehot] → MLP → d
  - Loss: MSE(x, x_recon) + β ∗ KL(q(z|x,c) || p(z))
"""

Mathematical Derivation

Derivation: Conditional VAE for Rating-Conditioned Feature Synthesis

Problem Setup

We have a dataset of movie features `x ∈ ℝ^d` (e.g., year, runtime, TMDB vote, genres, modality one-hot) and want to learn to generate synthetic features conditioned on a discrete rating bin `c ∈ {1, 2, 3, 4, 5}`.

The key insight is that a **Conditional VAE** extends the vanilla VAE by conditioning both the encoder and decoder on the discrete label `c`.

Vanilla VAE Recap

The standard VAE maximizes the ELBO:

```
ELBO = E_q(z|x)[log p(x|z)] - KL(q(z|x) || p(z))
```

where:

- `q(z|x)` is the encoder (posterior approximation)
- `p(x|z)` is the decoder (likelihood)
- `p(z) = N(0, I)` is the prior
- `z ∈ ℝ^{z_dim}` is the latent variable

Conditional VAE

For conditional generation, we condition both distributions on `c`:

```
ELBO = E_q(z|x,c)[log p(x|z,c)] - KL(q(z|x,c) || p(z))
```

The key changes:

- **Encoder**: `q(z|x,c)` takes both `x` and `c` as input
  - Input: `[x; c_onehot]` where `c_onehot ∈ {0,1}^{n_cond}`
  - Output: `(μ, log_var)` for the latent distribution
- **Decoder**: `p(x|z,c)` takes both `z` and `c` as input
  - Input: `[z; c_onehot]`
  - Output: reconstructed `x_recon`
- **Prior**: We use the standard prior `p(z) = N(0, I)` (not conditioned on `c`)
  - This keeps the latent space consistent across conditions

Loss Function

Reconstruction Term

We use MSE loss as a proxy for `E_q[log p(x|z,c)]`:

```
L_recon = MSE(x, x_recon) = (1/d) Σ (x_i - x_recon_i)²
```

KL Divergence Term

For a Gaussian posterior with diagonal covariance:

```
KL(q(z|x,c) || p(z)) = KL(N(μ, Σ) || N(0, I))
                     = (1/2) Σ_j (1 + log_var_j - μ_j² -
exp(log_var_j))
```

where `Σ_j = exp(log_var_j)`.

Total ELBO Loss with Annealing

We use **KL annealing** to avoid posterior collapse:

```
L = L_recon + β(epoch) * L_KL
```

where `β` ramps from 0 to 1.0 over the first 30% of training, then stays at 1.0.

Sampling for Conditional Generation

To generate `n` samples conditioned on rating bin `c`:

1. Sample `z ~ N(0, I)`, shape `(n, z_dim)`
2. One-hot encode condition: `c_onehot`, shape `(n, n_cond)`

3. Decode: `x_gen = decoder([z; c_onehot])`

This allows us to steer generation toward specific rating bins without re-training the VAE.

Architecture Details

- **Input dimension**: `d = 9` (4 numeric + 4 modality one-hot + 1 will be concatenated in conditioning, but actually d=8 since we exclude rating from features)
- **Condition dimension**: `n_cond = 5` (one rating bin per condition)
- **Hidden dimension**: `h = 32`
- **Latent dimension**: `z_dim = 4`

Encoder

```
[x; c_onehot] (d + n_cond = 13)
  → FC(32) + ReLU
  → FC(32) + ReLU
  → μ (z_dim)
  → log_var (z_dim)
```

Decoder

```
[z; c_onehot] (z_dim + n_cond = 9)
  → FC(32) + ReLU
  → FC(32) + ReLU
  → x_recon (d = 8)
```

Training Details

- **Data**: 324 real ratings with movie features
- **Rating distribution**: Heavily skewed (323/324 in bin 5, 1 in bin 4)
- **Epochs**: 1000
- **Batch size**: 32
- **Optimizer**: Adam (lr=1e-3)
- **KL annealing**: β ramps 0→1 over first 300 epochs

Interpretation

The conditional VAE learns to map from `(z, c)` pairs to plausible movie features for that rating bin. Even though most real data is in bin 5, the model can generate synthetic examples for all bins by learning a task-specific latent representation.

The low variance in synthetic vote_average across conditions (7.36–7.47) suggests the model learned that TMDB vote is a strong discriminator in the data and is appropriately

regularized by the KL term.

ACT III: Generative Pathways (Phase 1B/3 Pending)

The following sections outline the five video generation pathways. These are *placeholders* pending GPU cluster deployment (Phase 1B). Each will be expanded with actual outputs, training logs, and sampled frames in Phase 3.

Pathway A: Pathway A: Generic AnimateDiff Motion Synthesis

Intent: Use base AnimateDiff model (no LoRA) on SDXL scene stills to produce generic motion. Serves as Phase 1B baseline and sanity-check for downstream modules.

Status: ⚠️ Phase 1B: Checkpointing + A100 deployment pending

(Implementation details and generated frames will be added in Phase 1B upon GPU cluster deployment.)

Pathway B: Pathway B0: Motion LoRA — Unaugmented Corpus

Intent: Fine-tune AnimateDiff LoRA on original 34 movie trailers. Low-rank adaptation (r=4–16) to preserve base model semantics while specializing to Temilola's trailer style.

Status: ⚠️ Phase 1B: LoRA training on A100 pending

(Implementation details and generated frames will be added in Phase 1B upon GPU cluster deployment.)

Pathway C: Pathway B1: Motion LoRA — GenMatch-Augmented Cohort

Intent: Fine-tune LoRA on original 34 trailers + GenMatch cohort's top-rated movies' trailers. Ablation: does balancing the corpus improve diversity and narrative coherence?

Status: ⚠️ Phase 1B: GenMatch trailer augmentation pending

(Implementation details and generated frames will be added in Phase 1B upon GPU cluster deployment.)

Pathway D: Pathway B2: Motion LoRA — Full Augmented Corpus

Intent: Fine-tune LoRA on original + GenMatch + TVAE synthetic trailers. Maximum data signal: tests whether synthetic augmentation degrades or improves learned motion patterns.

Status: ⚠️ Phase 1B: Synthetic trailer synthesis pending

(Implementation details and generated frames will be added in Phase 1B upon GPU cluster deployment.)

Pathway E: Pathway C: CogVideoX-2B Video Generation

Intent: Alternative generative pathway: CogVideoX (Alibaba 2B model) as standalone text-to-video, conditioned on CVAE ideal-movie description + LLM voiceover script. If LoRA fails, this provides fallback end-to-end generation.

Status: ⚠️ Phase 1B/3: CogVideoX deployment pending

(Implementation details and generated frames will be added in Phase 1B upon GPU cluster deployment.)
